ABSTRACT

By using a series of diode sampling gates and capacitive storage elements to achieve the necessary time delay, a cancellation filter is designed that will give a maximally flat passband and that will give subclutter rejection at zero frequency and at harmonics of the pulse repetition frequency. Such a filter is necessary in each range channel of moving target indication (MTI) radar systems. Theoretical results obtained from digital simulation are compared with actual results obtained upon completion of the filter synthesis, and a brief evaluation of the entire range channel is presented.

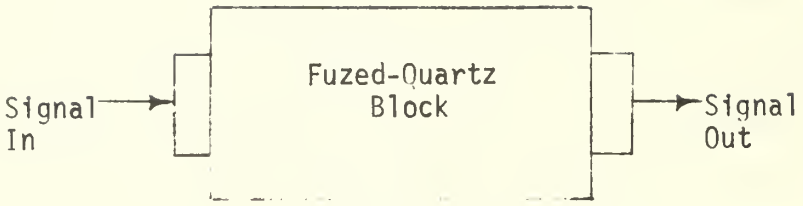
I. INTRODUCTION

The increased emphasis upon reducing size, weight and cost of components, coupled with the recent rise of integrated circuits as an efficient and reliable method of achieving the above three goals has paved the way for the revision of existing construction methods. With existing technology, MTI type radars presently use cancellation filters which involve the use of quartz or mercury delay lines. A typical quartz delay line is represented in Figure 1. The length of the time delay is proportional to the total acoustic path length, and hence to the number of times the signal is reflected from the facets or sides in the fuzed quartz block of the delay line.

A typical delay line itself weighs ten to fifteen pounds, and the actual package is twelve to eighteen inches in diameter and about one and one half inches thick. The cost of such a delay line ranges from several hundred to several thousand dollars. Thus if it were possible to perform the function of the delay line on integrated circuit chips, size, weight, and cost reduction could all be achieved, with the additional benefits of greater efficiency and much improved reliability. These chips could then be incorporated into an MTI radar, thereby achieving the desired goals of reduced size, weight and cost.

The use of MTI radar systems is important for discerning moving targets in the presence of fixed targets whose undesired radar returns may be much stronger than those of the moving targets. MTI operation



Basic type fuzed-quartz delay line

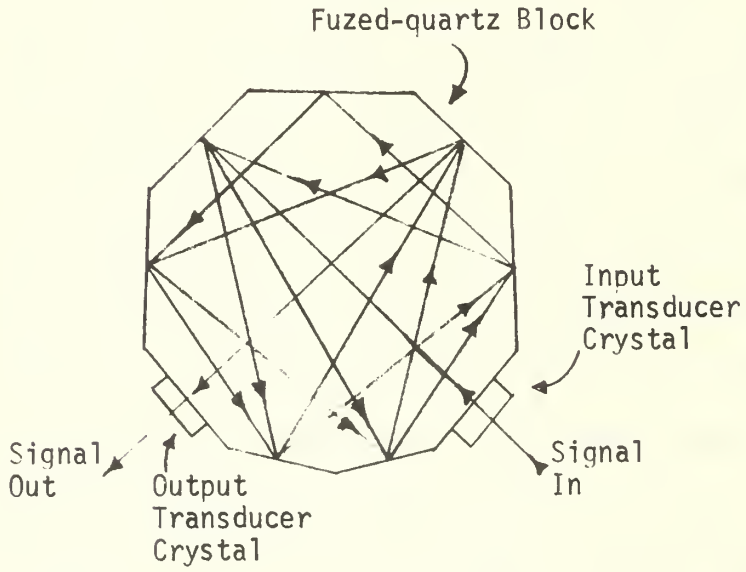


Fig. 1. Quartz delay line

is based on the fact that moving targets create a doppler frequency shift which is proportional to the radial component of velocity at which the target moves. Strong fixed target returns may camouflage weaker moving target returns, and therefore a cancellation filter which rejects these fixed echoes is necessary.

Present use of quartz or mercury delay lines in the cancellation filters of MTI systems gives moving target range information which is continuous. Thus, if any part of the filter is inoperable, the entire system ceases to function. If the range information were obtained from the composite output of a number of parallel range channels, one for each range, then even if one of the channels was inoperable, the majority of the information would still be available. Figure 2 indicates one of the necessary range channels of such a system. In addition to increasing the overall reliability of the system, the narrow range intervals allow for narrow band filtering without destroying any important range information. Timing circuits allow the bi-polar video input to be sampled in turn for successive range channels and then to be reconstructed at the output of the range channels.

The cancellation filter is discussed in the following chapters of this thesis, and the rest of the range channel is discussed in the thesis of E. L. Washam [Ref. 1].

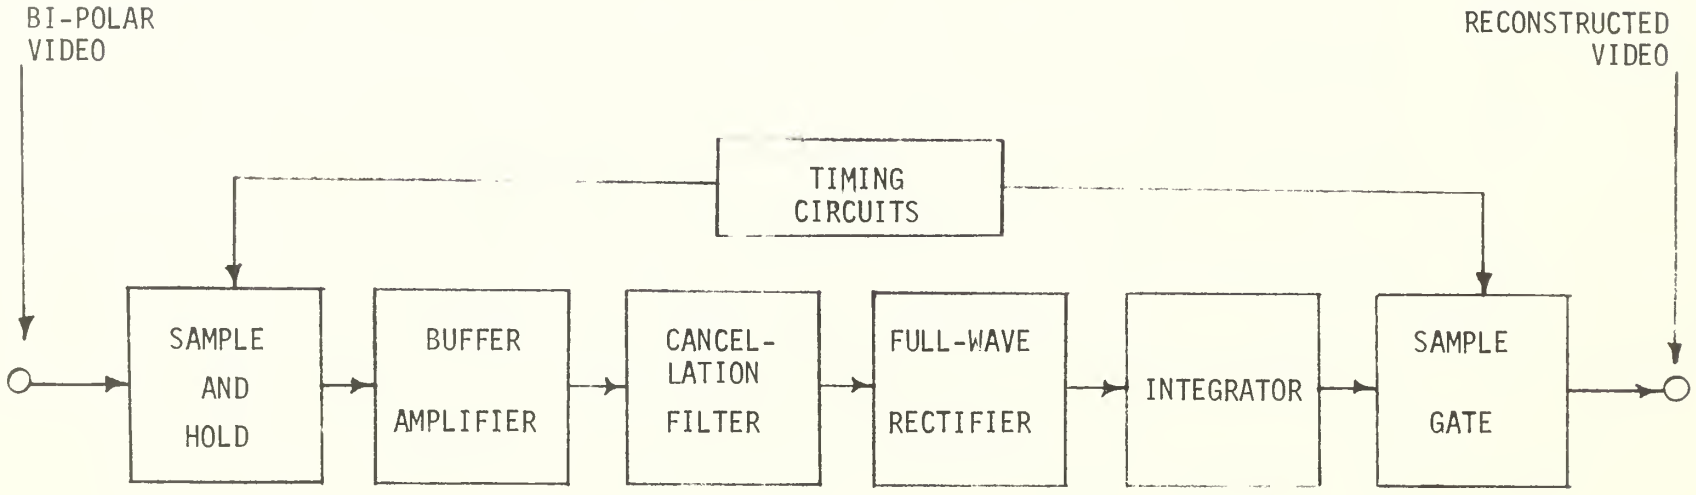

Fig. 2. Typical range channel

II. DESIGNING A CIRCUIT

In a paper by Warren D. White [Ref. 2], a transfer function, H(z), which gives the desired maximally flat passband and rejection of harmonics of the pulse repetition frequency is suggested. He indicates that the transfer function,

$$H(z) = \frac{(z-1)^3}{(z-.04)(z^2-.88z + .61)} , \qquad (1)$$

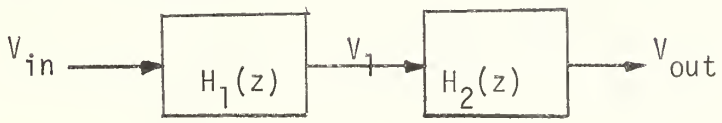
could best be synthesized in two parts; the first,

$$H_1(z) = \frac{z-1}{z-.04} , \qquad (2)$$

and the second,

$$H_2(z) = \frac{(z-1)^2}{z^2 - .88z + .61} \qquad (3)$$

In the above equations, $z = e^{j\omega T}$, where T is the reciprocal of the pulse repetition frequency. In block diagram form equations (1), (2), and (3) may be reduced to



In his book, Merrill I. Skolnik [Ref. 3] elaborates upon this block diagram, as seen in Figure 3 below.

The derivations of the transfer functions from Skolnik's block diagram are shown in Appendix A.

By simulating these block diagrams on the digital computer, frequency responses for the first stage, second stage, and complete circuit may be obtained. The computed data points from the simulated

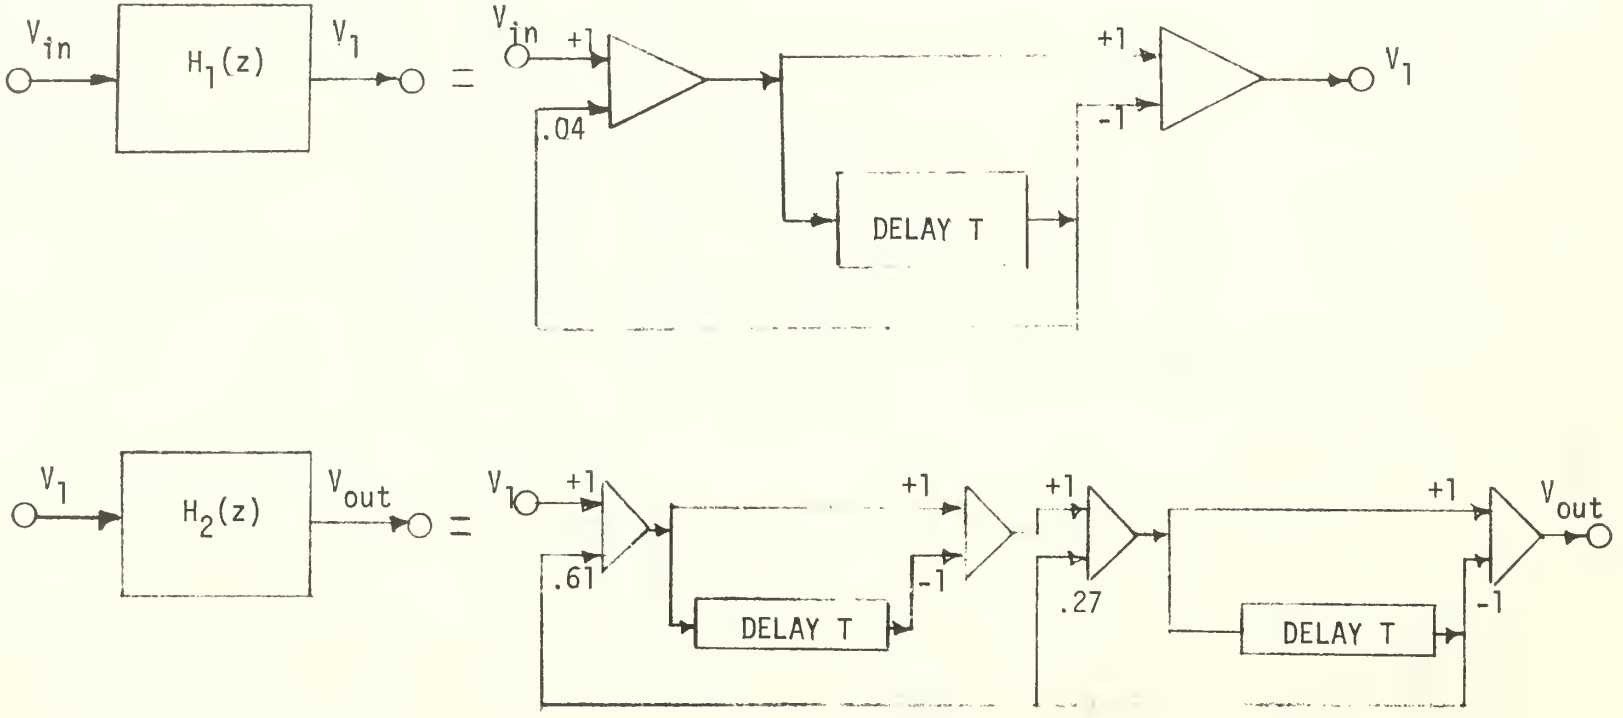


Fig. 3. Block diagrams of $H_1(z)$ and $H_2(z)$

system and corresponding frequency responses are shown in Appendix B. The response of stage one closely duplicates that of the positive portion of a sine wave which is shown in dashed lines on the first stage response. The effect of the small feedback factor is to bulge the frequency response somewhat. Once a working model of the filter is built, these responses will provide a basis for determining if the filter actually satisfies the requirements of the system.

The theoretical characteristics of this filter can be compared with those of simple RC differentiating filters of one, two and three stages and two cases of an integrator-summer circuit presented by Mitchell [Ref. 4]. The comparison shown in Figures 4a and 4b indicates that the cancellation filter gives the best combination of clutter rejection at zero frequency and maximum gain in the passband.

In order to synthesize such a filter, at least two decisions must be made. The first is to decide how to accomplish the required additions, and the second, and more complicated is to decide how to achieve the desired delay. For the AN/UPS-1, the pulse repetition frequency is 800 cycles per second, and the required delay is therefore 1.25 msec.

The problem of addition is easily solved by a form of collector summation. By having the voltages to be summed at the collectors of two separate transistors, addition may be obtained by applying these voltages to the top and bottom of a voltage divider. The center tap output will then be proportional to the sum of the two inputs. If the resistors are made equal, the output will equal one half of the

sum of the inputs, as seen in Figure 5 below. An amplifier stage may then be used to recover the voltage lost in the addition process.

One method of accomplishing the 1.25 msec delay is by the use of an artificial transmission line. However, delays of this magnitude would require either the use of a tremendous number of stages or the use of fewer stages containing unreasonable values of inductance. In addition, integrated circuit design favors the use of capacitors and resistors rather than inductors. Thus, the use of an artificial transmission line is impractical.

Another possibility, which proves to be feasible, involves the use of a sampling circuit and a series of switches each followed by a storage capacitor in which the signal component is stored for the required length of time, which in this case is 1.25 msec. The sampling circuit and the switches can be triggered by pulses separated in time by 1.25 msec. The value of the storage capacitor should be made small enough to give a fast charging time constant. It must, however, be large enough so that the input voltage level is maintained for the entire 1.25 msec with a minimum of droop due to discharge by leakage.

If the sampler and switches are gated on by the same set of trigger pulses, they will all be on simultaneously. Therefore, a fraction of the same sample voltage, depending upon the ratio of the capacitors, will appear on all storage elements, and no delay will take place.

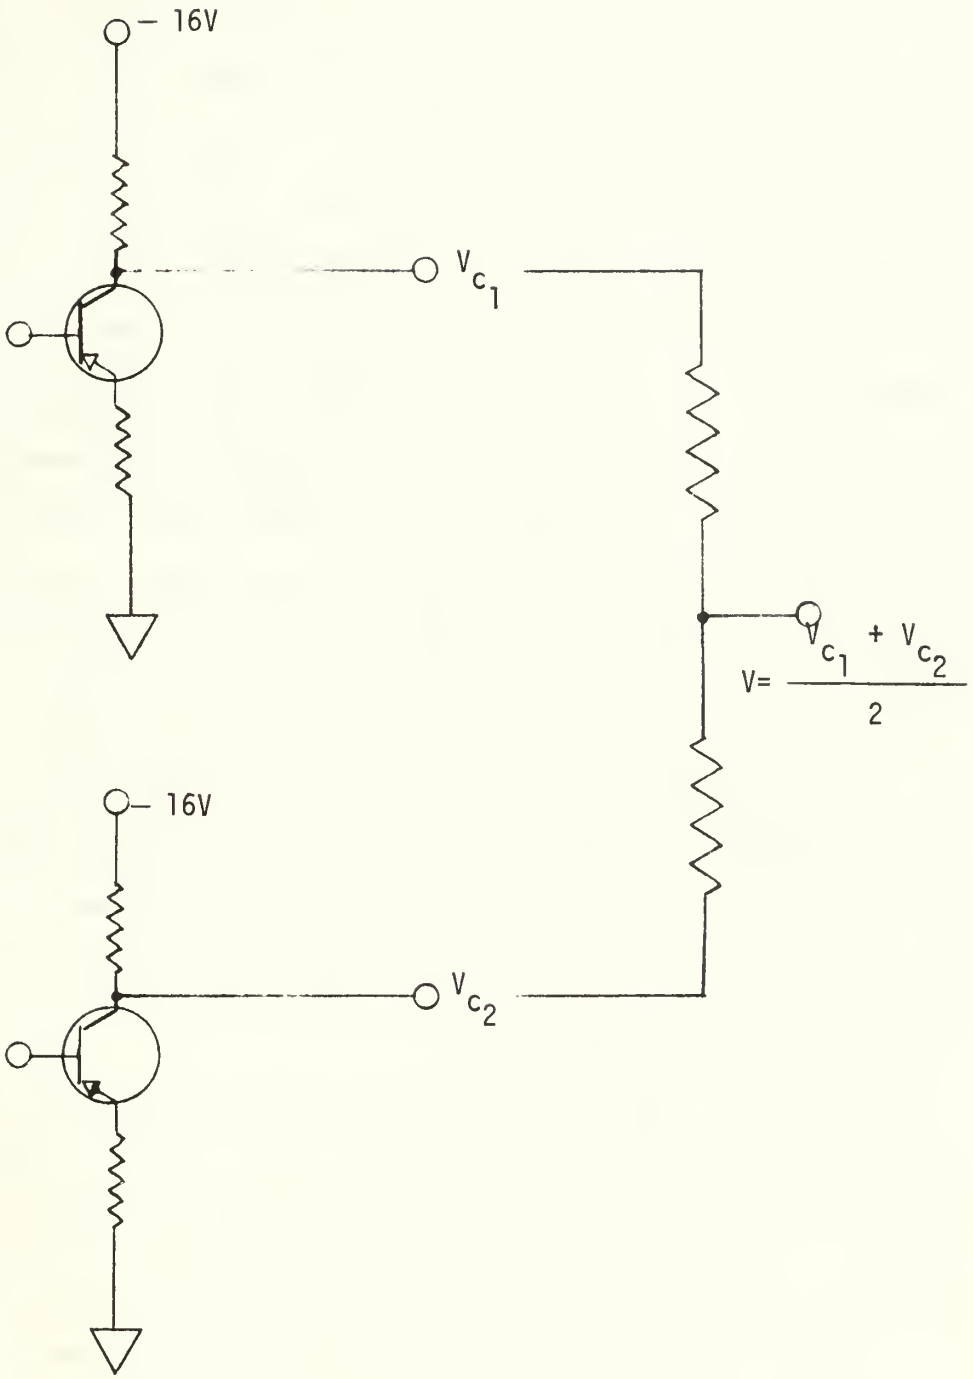

Fig. 5. Summing circuit

If, however, the switch following the sampling circuit is gated on by a pulse between basic range pulses occurring every 1.25 msec, then the delay can be achieved as indicated in Figure 6. This first switch can be triggered during the period when the sampler and second switch are gated off. For example, if the trigger pulses for the sampling circuit and the second switch are 100 μsec in duration, then these elements are gated off for 1.15 msec. If the first switch is triggered at any point within this interval, then a capacitive ratio of the original sample value voltage will appear at the storage element of this switch. When the original trigger pulse gates on the sampling circuit and the second switch again, a new sample value appears at the storage element of the sampling circuit and a fraction of the original sample voltage appears at the storage element of the second switch. Amplification stages are necessary to recover the voltage lost when the sampler and the switches are gated on. The amplified output at the storage element of the second switch is now delayed 1.25 msec from the sample voltage at the output of the sampling circuit. These sample voltages may now be added with opposite polarity in order to achieve the delay cancellation required in the block diagram of Figure 3.

The delayed trigger pulses mentioned above may be easily obtained by triggering a monostable multivibrator with the trailing edge of the trigger pulse used both on the sampling circuit and the second switch. By differentiating the positive trigger pulse, two spikes are obtained. The positive spike may be eliminated by the use of a diode in parallel with the resistor in the differentiating circuit

as shown in Figure 7. This negative spike is delayed by the width of the triggering pulse, and when it is applied to the monostable multivibrator it yields a positive delayed pulse at the collector of one transistor and a negative delayed pulse at the collector of the other. The width of these pulses is determined by the time constant built into the multivibrator.

The respective feedback factors may be obtained by attenuation of the output of the proper delay circuitry in accordance with Figure 3. These voltages may be added to the input of the delay circuitry by the method shown in Figure 5. Feedback oscillation is not an important consideration here since the feedback factors are less than unity.

If the sampler and switch circuits are chosen properly, this form of delay line will lend itself well to integrated circuit conversion. If, for example, an electromechanical chopper were to be used for either the sampler or the switch, this adaptability would be lost. While the electromechanical chopper is an ideal switch in that it is characterized by extremely high off impedance in the order of thousands of megohms and a very low on impedance of milliohms, it is relatively slow and bulky and would not convert readily to integrated circuit design.

The simplest type of sampler or switch is the solid-state-diode bridge. The diode bridge is extremely economical and is faster than the electromechanical types. Diode bridges are best suited for signals in excess of 100 mV, and since the input to this circuit will be typically five to ten times that amount, it is

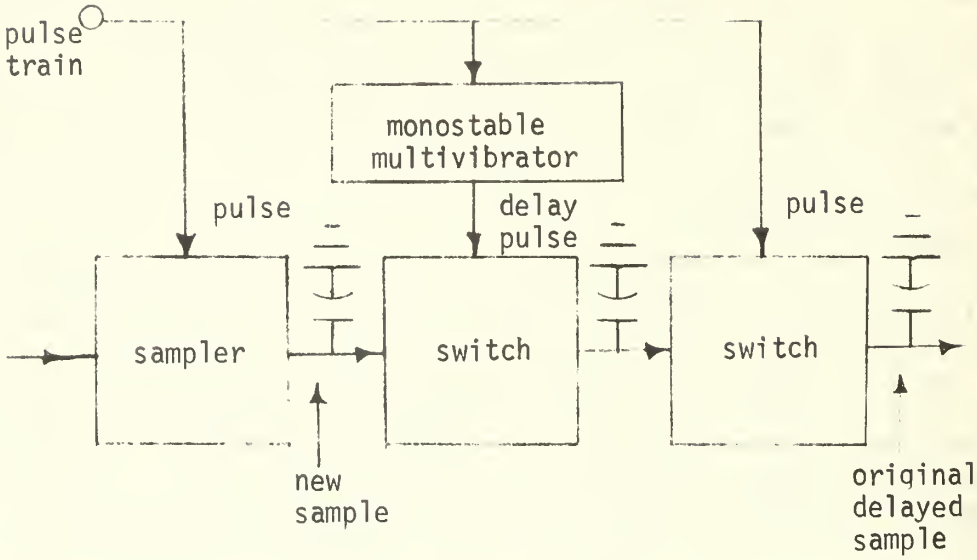

Fig. 6. Delay schematic

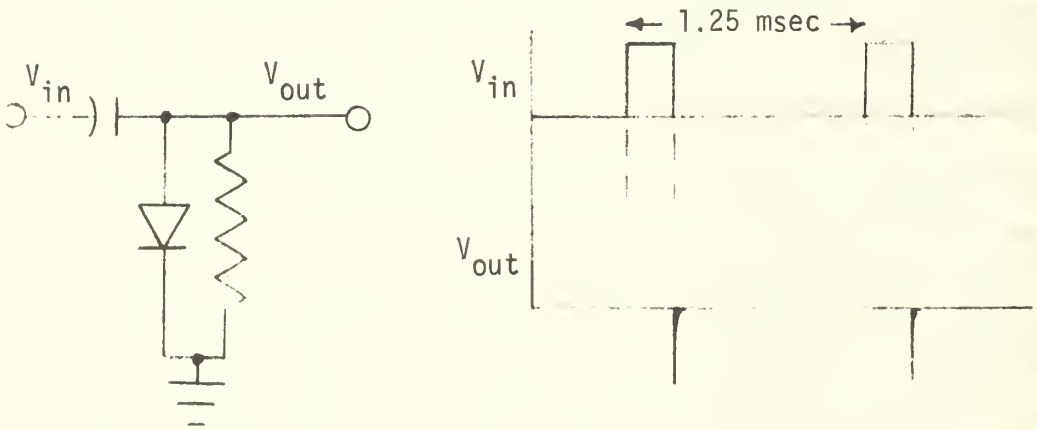

Fig. 7. Differentiating circuit with input and output

ideally suited for this application. Although not as good in this respect as is the electromechanical chopper, the diode bridge also has an extremely high off impedance and a low on impedance.

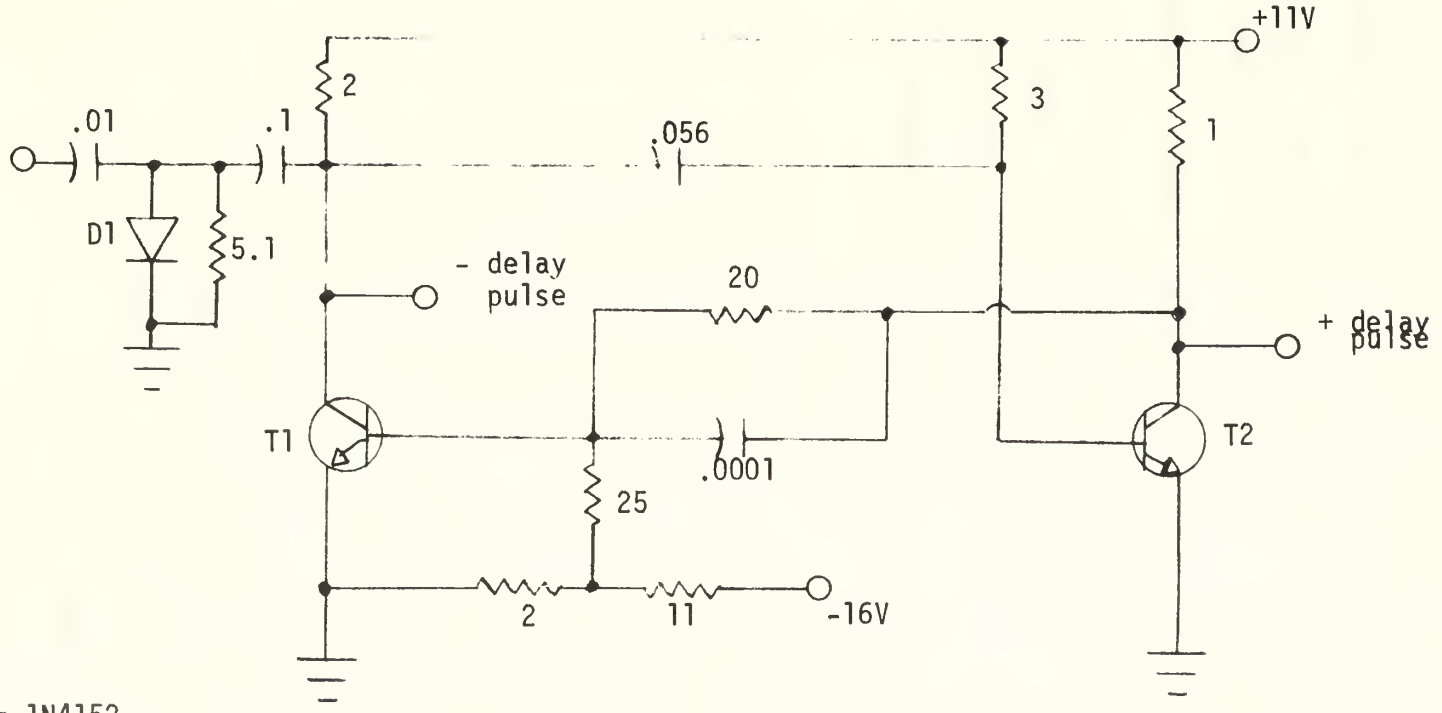
Since the diode bridge fulfills the requirements imposed upon it by the circuit, and since it also converts easily onto an integrated circuit chip, its choice is ideal for employment in the building of the proposed delay line.

III. BUILDING THE CIRCUIT

Since the expected input from the buffer amplifier in Figure 2 will vary in range from one half to one volt peak superimposed on a negative d-c value, a reasonable test input signal would be a sinusoid superimposed upon a negative d-c level. Using this test voltage, it is now possible to start building the circuit.

Before any evaluation of the delay line discussed in Chapter II is possible, it is necessary to build a monostable multivibrator to give the delayed pulses necessary for triggering the first diode switch. Many authors discuss multivibrator circuits and their application. Oppenheimer [Ref. 5] describes a monostable multivibrator which is exactly what is needed in this case. The multivibrator is triggered by a negative spike and gives positive and negative pulses at the collectors of the two transistors. The pulses are not perfectly square because by using values of capacitance and resistance such that the RC time constant forces one pulse to be square, it also causes deterioration of the other pulse. Since perfectly square pulses are not necessary, a compromise may be reached whereby both pulses are relatively square with a minimum of sag. The circuit diagram for the monostable multivibrator is shown in Figure 8.

With a pulse generator supplying positive and negative pulses and the multivibrator supplying positive and negative delayed pulses, the delay line itself may be started. Since the input to the delay line



D1= 1N4152
T1= T2= 2N337
ALL CAPACITORS IN μf
ALL RESISTORS IN KΩ

Fig. 8. Monostable multivibrator

is composed of the input signal plus a fraction of the delayed output signal, a partial summation circuit can be used as an input to the delay stage until the feedback fraction is generated.

Because the input will be between one half and one volt peak, the gain on the test signal oscillator may be set randomly within this range. This sinusoid may then be amplified to approximately two volts peak to give a workable signal to the rest of the circuit. The collector output can be applied to the top of a voltage divider with the bottom grounded and the output taken off the center tap. The required fraction of output voltage can be added to the bottom of the voltage divider once the voltage fraction has been generated. This center-tap output can now be applied to the diode-bridge sampling gate. This circuit is shown in Figure 9.

The signal applied to the diode sampling gate must have a d-c return tied to ground so that the sampled signal is passed undistorted. Switching diodes are used to obtain rapid opening of the diode bridge. The diode sampling gate itself is complete once the trigger pulses are applied to it. The circuitry of a typical diode bridge is shown in Figure 10, and is the same for all diode bridges in the system, although there are some differences in pulses applied to them.

The signal sample obtained through the diode bridge is stored on a capacitor and is then transferred through the delay bridge to a second storage capacitor. At this point it becomes necessary to incorporate isolation circuits. Within each delay line the sampling gate and the second switch are being gated on by the same trigger

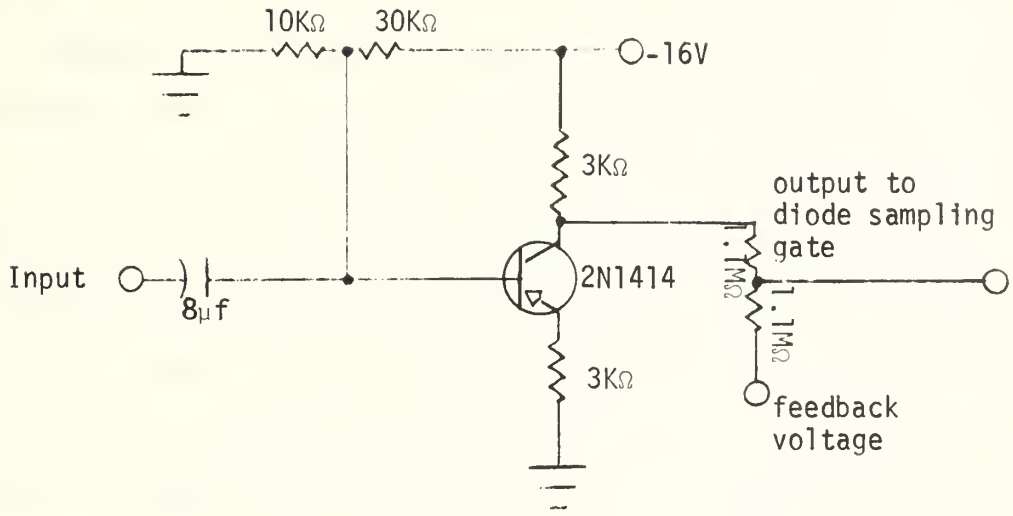


Fig. 9. Input amplifier and partial addition

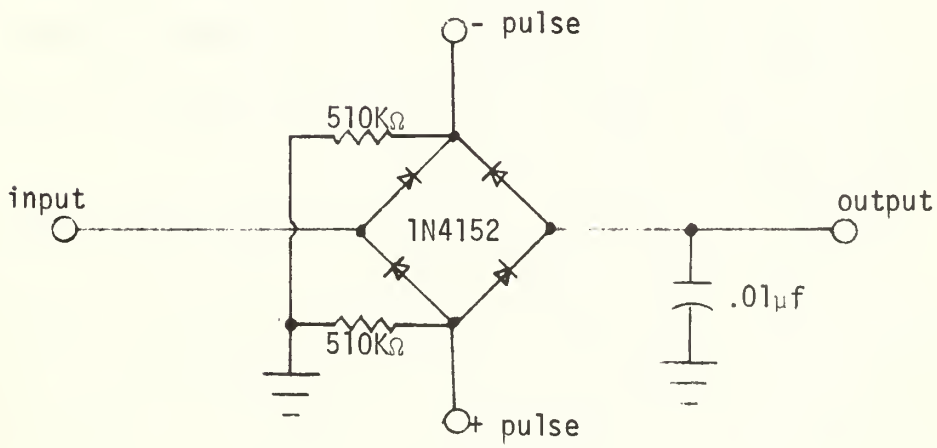

Fig. 10. Typical diode bridge

pulses. During the on time all four points in the delay bridge are connected together through low-impedance diodes. If no isolation were provided the input half of the sampling bridge would be coupled to the output half of the second diode switch, and its output would not be a delayed replica of the input, but rather the input itself.

To prevent shorting of input to output, pulse isolation circuits are incorporated between successive diode bridges using the same trigger pulses. Since the block diagram calls for three delay lines, there will be six bridges gated by trigger pulses and three bridges gated by the delayed trigger pulses. The pulses triggering each of the six undelayed diode bridges will have to be isolated from each other as will the delayed pulses triggering the three delay bridges. The isolation circuits used are the simple transistor configurations shown in Figure 11 and Figure 12.

The output of the third diode bridge is a replica of the output of the first diode bridge but delayed in time by 1.25 msec. This final output is now attenuated to give the proper feedback fraction and added to the input of the delay line by adding it to the bottom of the voltage divider in Figure 9.

This portion of the complete circuit can be tested by itself. The response should remain essentially constant throughout the frequency range with only a slight dip at mid-frequencies. By the comparison shown in Figure 13, it is seen that at frequencies in the vicinity of 400 cycles per second, the response drops below the theoretical. At low frequencies or as the frequency approaches the pulse repetition frequency there are many samples during each cycle

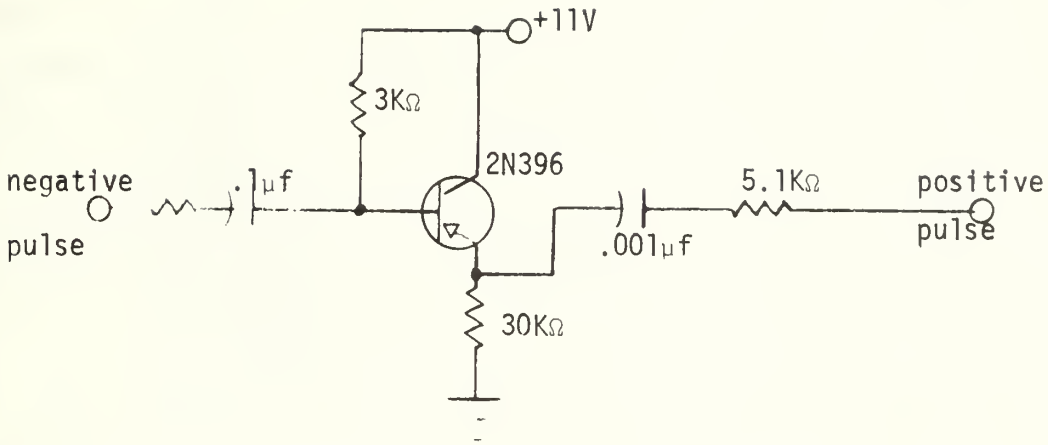

Fig. 11. Negative pulse isolation

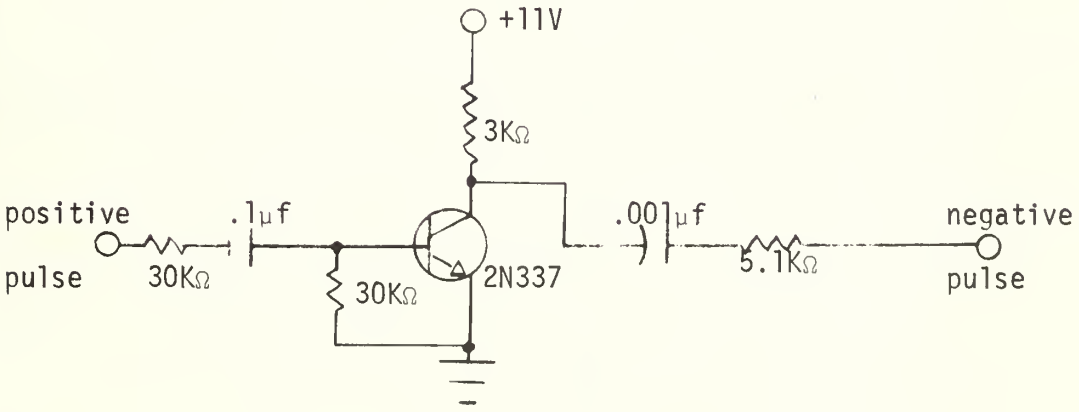

Fig. 12. Positive pulse isolation

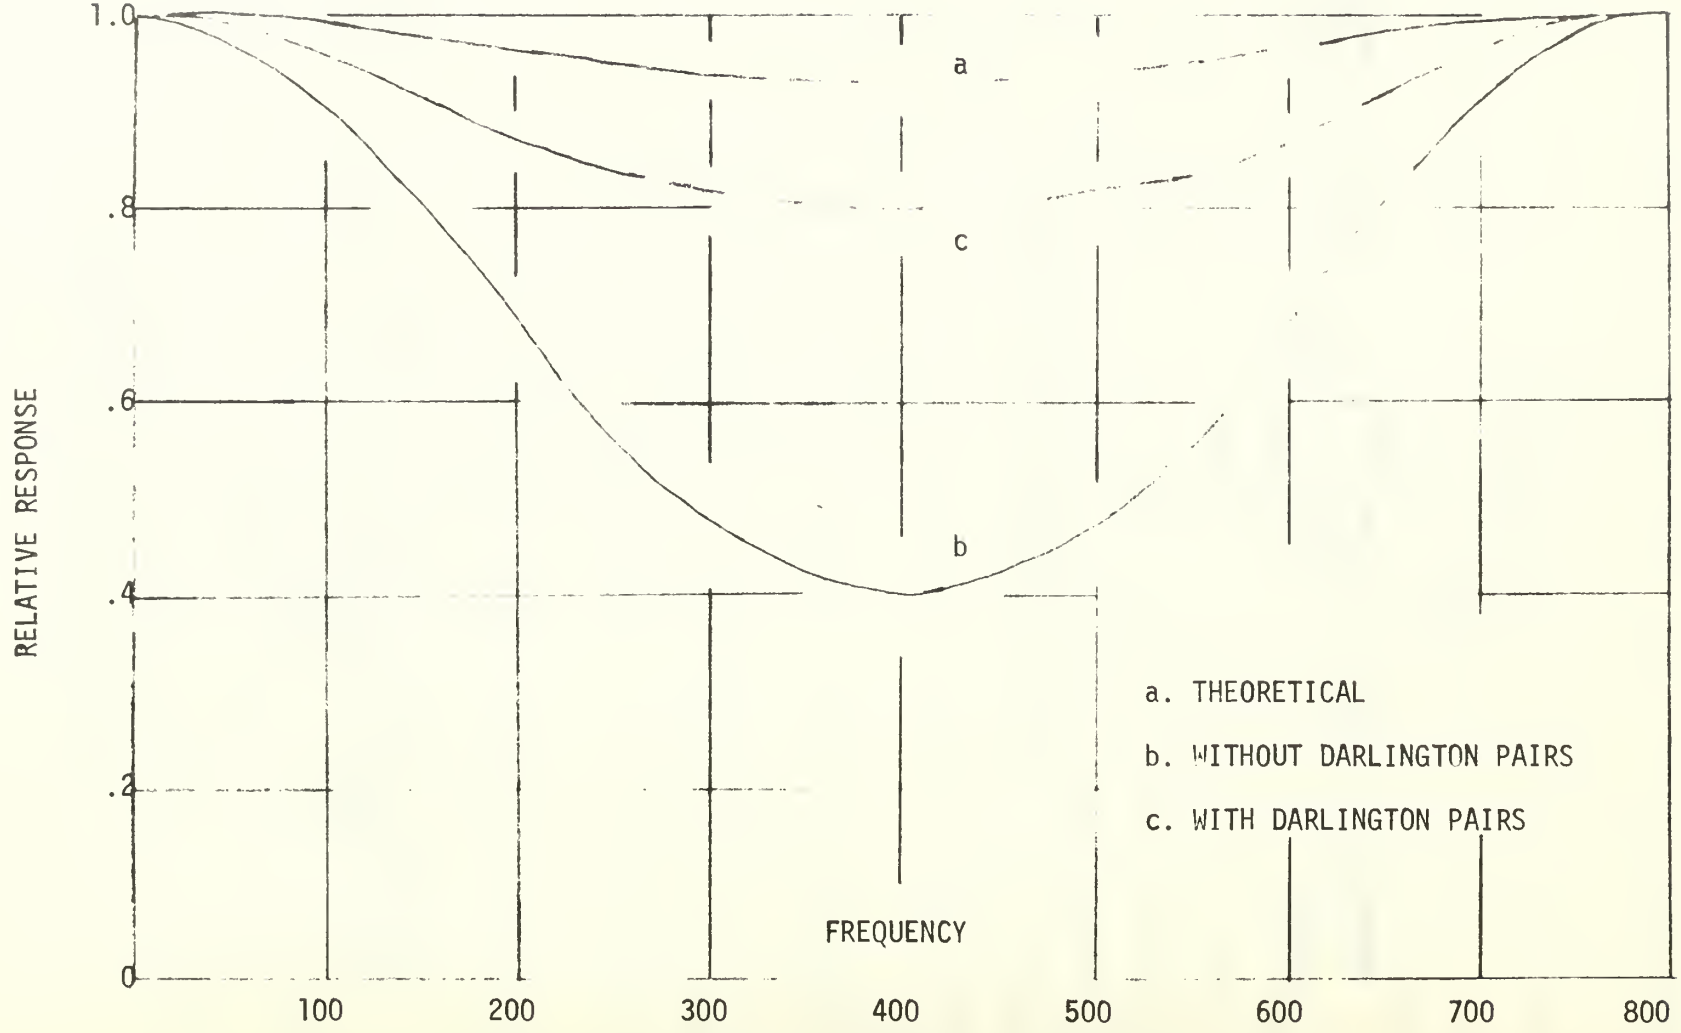

Fig. 13. Frequency comparison

of the sine wave and the capacitor is forced to accept only small changes in voltage between each sample. Near 400 cycles per second there are two samples during every cycle of the input sine wave. Therefore, at the storage capacitor, the voltage may have to change between the maximum positive excursion and the maximum negative excursion of the input sinusoid, depending upon the phase relationship. If the samples are occurring at 90^{o} and at 270^{o} on the sine function, then the maximum change takes place. If the samples occur at 0^{o} and 180^{o} on the sine function then the output is zero. Thus, the storage capacitor sometimes has to change between the positive and negative average values of the sine wave, but when sampling occurs at 0^{o} and 180^{o}, the samples are all zero no matter how large the sine wave. It is possible to force the capacitor to accept the large mid-frequency voltage excursions that may occur by increasing the current drive through the diode bridge during the on period. One method of doing this is to place Darlington pairs before each diode bridge. Thus when each bridge is gated on, the current drive through the gate and to the storage element is much greater than before. This enables the storage element to accept all voltage changes whether they are small as at low frequencies or frequencies near the pulse repetition frequency or high as will be the case near 400 cycles per second. Figure 14 shows the Darlington pair configuration which precedes each diode bridge in the circuit.

The current gain for a Darlington pair is β^{2}, and the large emitter resistors cause most of the amplified current to charge the

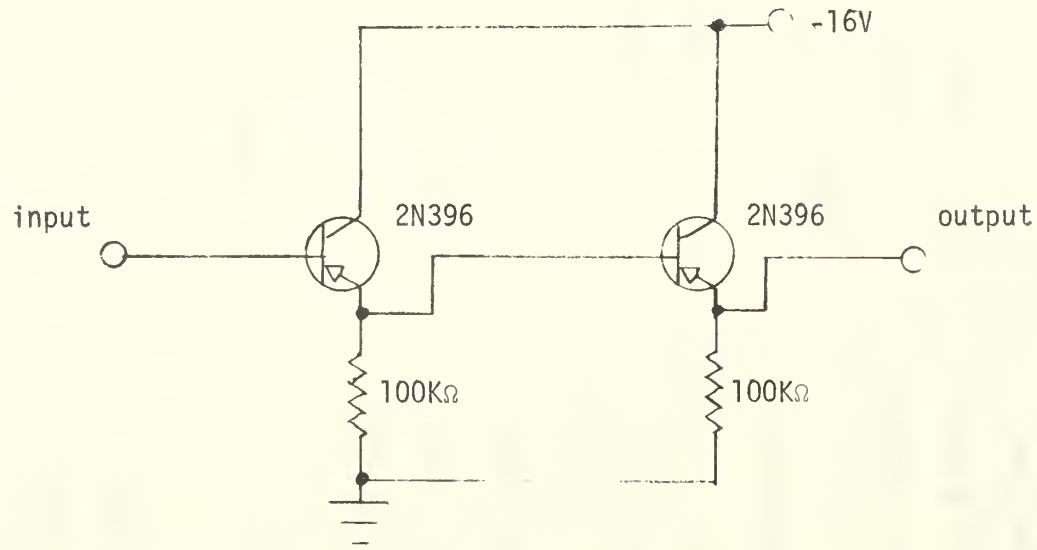

Fig. 14. Darlington pair

storage capacitor during the gated on period since only a small portion of it is bled off through the resistors to ground. With the Darlington pairs, the frequency response is much improved over that obtained without them.

With the proper amplification to regain any voltage lost through the delay line and to invert the signal, delay cancellation may be achieved by the method shown in Figure 5. For an input sine wave at a frequency of 80 cycles per second, there will be ten samples on every cycle. The wave forms for the positive input signal, negative delayed signal and the sum of the two signals for the given conditions are shown in Figure 15. The output of the summation process is extremely small due partially to the fact that the cancellation results in a small signal and secondly that the method of addition yields only one half of the sum. This loss of amplitude necessitates the use of an additional amplifier stage to give an output large enough to drive the rest of the filter. The collector output of this amplifier stage is the value V_1 shown in Figure 3. The complete circuit diagram is shown in Figures 16a and 16b. The monostable multivibrator and all the pulse isolation circuits are omitted since they have already been shown, and would only confuse the diagram.

The second stage of the filter is simply a reproduction of the first stage with slight variations. In the first stage the feedback fraction is generated from the output of the delay line. In the second stage there are two delays, but only the final one generates the feedback voltages. It is therefore necessary to have two

amplifier stages each fed by the output of the final delay line in order to obtain the proper values of voltage to be added with the respective delay-line inputs.

As in stage one, the second stage requires that each trigger pulse be isolated from the preceeding one, Darlington pairs be used to increase the current drive to the storage elements, and amplifiers be used to regain voltage lost in the various addition stages. A circuit diagram for stage two is shown in Figures 17a through 17d.

Polaroid pictures of the sinusoid input to the circuit and the output at various frequencies are shown in Appendix C. The likeness between the first and second halves of the response over the frequency range of interest can be seen by comparing zero and 800 cycles per second, 100 and 700 cycles per second, 200 and 600 cycles per second, and 300 and 500 cycles per second. This response then repeats itself at intervals of 800 cycles per second.

IV. COMPARISON WITH THEORETICAL

In order to evaluate the effectiveness of the filter, the design and construction of which was described in Chapters II and III, it is necessary to compare its frequency response with the theoretical responses shown in Appendix B.

Trying to read voltage values from the oscilloscope is inaccurate and not suitable for taking the required frequency response. A vacuum-tube voltmeter (VTVM) is much more reliable. By taking the ratio of output to input at various frequencies between zero and 800 cycles per second and normalizing the results, a graph of relative response versus frequency can be plotted. The experimental data for stage one, stage two and for the entire circuit is shown in Tables I, II and III respectively, and the plots corresponding to this data are shown in Figures 18, 19 and 20.

The most noticeable discrepancy between the theoretical and the designed filter is the droop at mid-frequencies. Theory shows that the relative response for the filter at 400 cycles per second should be about .99. The cancellation filter falls to slightly less than .7 at this frequency. The fault can be traced in part to the second-stage frequency response, which falls .21 below the theoretical value. This points out that the problem of the large voltage change across the storage capacitor at mid-frequencies is not completely solved by the Darlington pairs. Since the phase relationship between the input test sine wave and sampling times is not

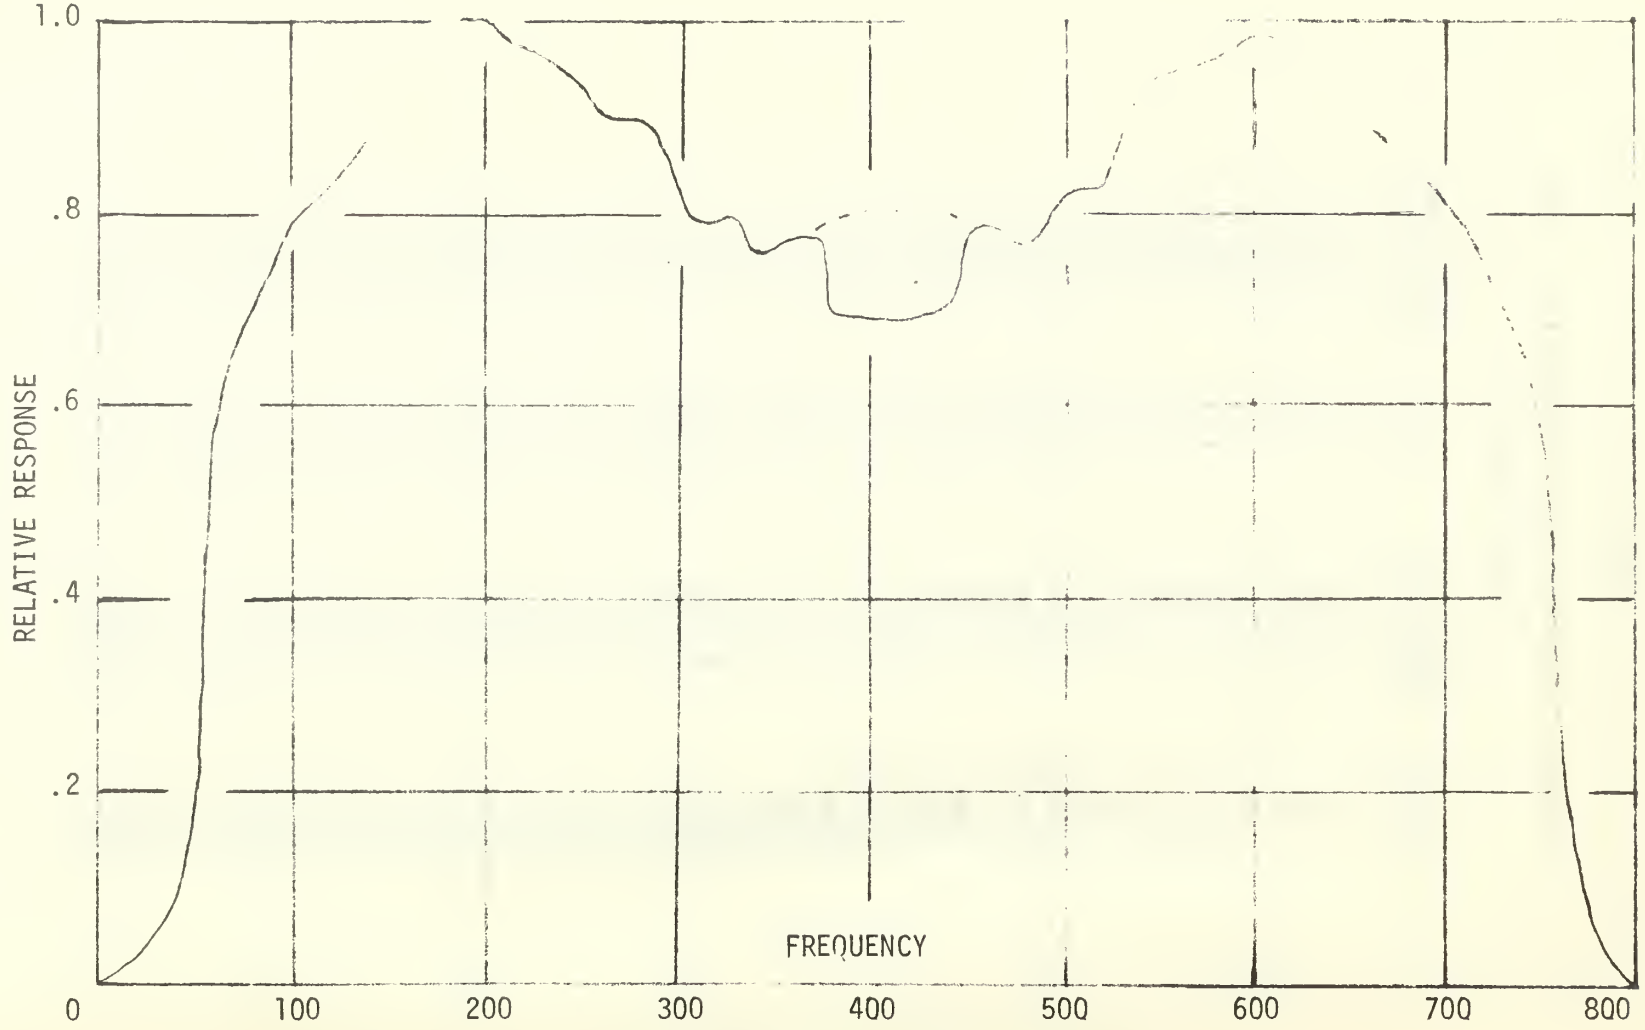

Fig. 20. Entire circuit response

always optimum near 400 cycles, the output would be expected to fall off somewhat. For this reason, the values recorded in the vicinity of 400 cycles per second fall off. By referring to Figure 19 and Figure 20 it is seen that for frequencies between 340 cycles per second and 510 cycles per second on the second-stage response, and for frequencies betwen 380 cycles per second and 440 cycles per second on the final response, the data changes radically from the established trends indicated by dashed lines on the respective responses.

The peaks of the passband for the cancellation filter occur 40 cycles per second closer to mid-frequency than calculations would indicate. This shift is not overly harmful since the filter response retains high passband characteristics over approximately the same range as the theoretical model.

Half-power points are another area for comparison. The model has half-power points at 105 cycles per second and 695 cycles per second, while in the cancellation filter they occur at 60 cycles per second and 750 cycles per second. The wider passband, however, does not destroy the rejection bands at zero and multiples of the pulse repetition frequency. Although not quite as good as the calculated values, the amount of clutter rejection given by the filter is still substantial.

Since the filter was built on vector board and never reduced to a prototype, some of the discrepancies between the theoretical and actual frequency responses may be due to poor connections associated with unsoldered joints and to the stray capacitances associated with the long wires.

A greater part of the discrepancy is probably due to inaccuracy in the voltages being added in the summing circuits, especially those circuits that perform the cancellation. In these circuits the delayed voltage must be an exact negative replica of the undelayed voltage in order for exact cancellation to take place as in Figure 15. If this is not the case, then the output voltage will be distorted and will have a significant effect on the performance of the rest of the circuit.

Whether these voltages are exact negative replicas of one another depends largely on the storage capacitors in the delay line. These storage elements are not high-precision capacitors and are marked as being accurate to only ±10% of their rated value. Thus although the discharging time constant may calculate to be exactly the same for all the storage elements in the delay line, they may be quite different and give more voltage droop due to discharge on some capacitors than on others. The amount of droop associated with each storage element is critical in establishing exact cancellation at the output of the delay line.

The problem of droop on the storage capacitor may be solved in any future attempts at bettering this circuit design by substituting metal-oxide-semiconductor field effect transistors (MOSFET) for the diode bridges. Although the diode bridges have low on impedance, the MOSFET has even lower on impedance and is therefore better suited for this application.

In addition to simplifying the circuit and reducing the area required for integrated circuit conversion, the MOSFETs will allow

a smaller storage capacitor to be used without permitting any droop in the voltage sample to take place. The smaller capacitor coupled with the Darlington pairs will further improve the frequency response near 400 cycles per second. For further information and explanation of MOSFETs see the paper by Burd and Sear [Ref. 6].

Since this filter was designed to be used in conjunction with the range channel built by E. L. Washam, a final evaluation of it may be made by actually inserting it into Washam's range channel. With a sinusoid test voltage as the input to the entire range channel, the system functions as would be expected. Any input frequency which lies within the passband of the cancellation filter appears at the output of the range channel as a voltage pulse indicating the presence of a target within the range of this channel. Frequencies near zero or near multiples of the pulse repetition frequency corresponding to fixed target clutter are rejected by the filter, and no output appears.

Time limitations prevented incorporation of the combined range channel into a transmitting MTI radar, but since the system responded as expected to the input test sine wave, it should also perform as required in the radar.

V. CONCLUSION

This thesis was motivated by the possibility of building a cancellation filter which could be fabricated on integrated circuit chips and which would be suitable for use in a range channel of an MTI radar. It has been shown that this filter provides the relatively flat passband which is desired and the necessary rejection at zero frequency and at integer multiples of the pulse repetition frequency.

The use of enough range channels to cover the entire distance corresponding to the maximum range for MTI operation is necessary to complete the range-gated filter. The maximum range for most radars and in particular MTI type radars is less than the range corresponding to the reciprocal of the pulse repetition frequency. Each one of these range channels requires a cancellation filter with the above characteristics. If, for example, each range channel covered 2 μsec, then 480 cancellation filters would be necessary to cover a maximum range of 80 nautical miles. Beyond this range fixed clutter is seldom a problem, and normal video could be used.

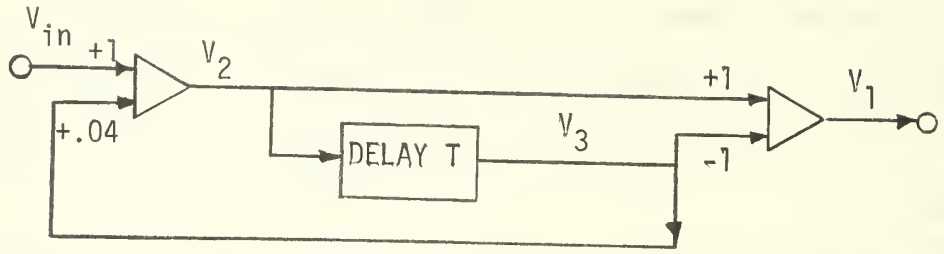
Since the above filter was designed with integrated circuitry in mind, the amount of space required by this number of integrated circuit chips would still be many times less than that taken by the three quartz delay lines required to obtain the same frequency response. The cost of the integrated circuit chips should be much less than the quartz delay lines with the added benefits of reduced weight and improved reliability.

The quartz delay line by itself is highly reliable, but since there is a large amount of attenuation associated with it, much amplification is necessary. These amplifier stages are subject to failure, and a breakdown anywhere in the system renders it inoperable. On the other hand, if one range channel breaks down the rest of the system is still functional, sacrificing less than one percent of its efficiency.

It has been demonstrated that circuits of a type that could be manufactured in integrated circuit form can be used to perform the functions of the quartz delay lines. But before such integrated circuits are made, it would be beneficial to do further research and development on the above circuit design, especially with respect to the possibility of including MOSFETs in the gating circuits.

APPENDIX A

DERIVATION OF TRANSFER FUNCTIONS



$$V_3 = (V_{in} + .04V_3)e^{-j\omega T}$$

$$V_3 = V_{in}e^{-j\omega T} + .04V_3e^{-j\omega T}$$

$$V_3(1 - .04e^{-j\omega T}) = V_{in}e^{-j\omega T}$$

$$\frac{V_3}{V_{in}} = \frac{e^{-j\omega T}}{1 - .04e^{-j\omega T}}$$

$$V_1 = (V_{in} + .04V_3)(1 - e^{-j\omega T})$$

$$V_1 = V_{in}(1 + .04\,\frac{V_3}{V_{in}})(1 - e^{-j\omega T})$$

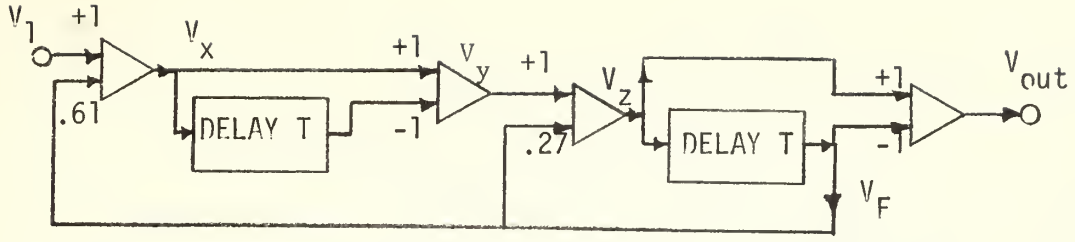
$$V_1 = V_{in}[1 + .04(\frac{e^{-j\omega T}}{1 - .04e^{-j\omega T}})]\ (1 - e^{-j\omega T})$$

$$V_1 = V_{in}(1 + \frac{.04e^{-j\omega T}}{1 - .04e^{-j\omega T}})\ (1 - e^{-j\omega T})$$

$$\frac{V_1}{V_{in}} = \frac{1 - .04e^{-j\omega T} + .04e^{-j\omega T}}{1 - .04e^{-j\omega T}}\ (1 - e^{-j\omega T})$$

$$\frac{V_1}{V_{in}} = \frac{1 - e^{-j\omega T}}{1 - .04e^{-j\omega T}} = \frac{e^{j\omega T} - 1}{e^{j\omega T} - .04}$$

$z = e^{j\omega T}$ $\qquad H_1(z) = \dfrac{V_1}{V_{in}} = \dfrac{z - 1}{z - .04}$



$$V_y = (V_1 + .61V_F)(1 - e^{-j\omega T})$$

$$V_z = (V_1 + .61V_F)(1 - e^{-j\omega T}) + .27V_F$$

$$V_F = [(V_1 + .61V_F)(1 - e^{-j\omega T}) + .27V_F]\, e^{-j\omega T}$$

$$V_F = [.61(1 - e^{-j\omega T}) + .27]\, e^{-j\omega T} V_F + V_1(1 - e^{-j\omega T})\, e^{-j\omega T}$$

$$\frac{V_F}{V_1} = \frac{(1 - e^{-j\omega T})\, e^{-j\omega T}}{1 - [.61(1 - e^{-j\omega T}) + .27]\, e^{-j\omega T}} = \beta(1 - e^{-j\omega T})$$

$$V_{out} = V_1\left[\left(1 + .61\,\frac{V_F}{V_1}\right)(1 - e^{-j\omega T}) + .27\,\frac{V_F}{V_1}\right](1 - e^{-j\omega T})$$

$$\frac{V_{out}}{V_1} = [1 + .61\beta(1 - e^{-j\omega T}) + .27\beta](1 - e^{-j\omega T})^2$$

$$\frac{V_{out}}{V_1} = (1 + .88\beta - .61\beta e^{-j\omega T})(1 - e^{-j\omega T})^2$$

$$\beta = \frac{e^{-j\omega T}}{1 - [.61(1 - e^{-j\omega T}) + .27]\, e^{-j\omega T}}$$

$$\beta = \frac{1}{e^{j\omega T} - .88 + .61e^{-j\omega T}}$$

$$\frac{V_{out}}{V_1} = \left[1 + \frac{(.88 - .61e^{-j\omega T})}{e^{j\omega T} - .88 + .61e^{-j\omega T}}\right](1 - e^{-j\omega T})^2$$

$$\frac{V_{out}}{V_1} = \frac{e^{j\omega T} - .88 + .61e^{-j\omega T} + .88 - .61e^{-j\omega T}}{e^{j\omega T} - .88 + .61e^{-j\omega T}}\,(1 - e^{-j\omega T})^2$$

$$\frac{V_{out}}{V_1} = \frac{e^{j\omega T}}{e^{j\omega T} - .88 + .61e^{-j\omega T}} \left(1 - e^{-j\omega T}\right)^2$$

$$\frac{V_{out}}{V_1} = \frac{\left(1 - e^{-j\omega T}\right)^2}{1 - .88e^{-j\omega T} + .61e^{-j2\omega T}}$$

$$\frac{V_{out}}{V_1} = \frac{\left(e^{j\omega T} - 1\right)^2}{\left(e^{j\omega T}\right)^2 - .88e^{j\omega T} + .61}$$

$$z = e^{j\omega T}$$

$$H_2(z) = \frac{V_{out}}{V_1} = \frac{(z - 1)^2}{z^2 - .88z + .61}$$

$$H(z) = H_1(z)\, H_2(z) = \frac{(z - 1)^3}{(z - .04)\,(z^2 - .88z + .61)}$$

13. ABSTRACT

By using a series of diode sampling gates and capacitive storage elements to achieve the necessary time delay, a cancellation filter is designed that will give a maximally flat passband and that will give subclutter rejection at zero frequency and at harmonics of the pulse repetition frequency. Such a filter is necessary in each range channel of moving target indication (MTI) radar systems. Theoretical results obtained from digital simulation are compared with actual results obtained upon completion of the filter synthesis, and a brief evaluation of the entire range channel is presented.
